\begin{abstract}
We present a novel numerical algorithm to perform nonlinear topology optimization on elastic thin shells. The main component of our method is a differentiable thin-shell simulator based on discrete differential geometry (DDG) discretization and the projected Newton method to solve geometrically nonlinear elasticity and its derivatives on a triangle mesh. We build a density-based topology optimization algorithm, enhanced by a density filter and a Heaviside projection scheme, to emerge and optimize topologically complex shell structures on curved surfaces. We validate our approach using standard test cases for nonlinear topology optimization and demonstrate the efficacy of our method by tackling highly nonlinear topology optimization problems by producing complex and high-resolution shell structural designs under various load conditions.
\end{abstract}

1. Introduction

Thin-shell structures manifest outstanding stiffness-to-weight ratios compared with their volumetric counterparts and therefore have played an essential role in many weight-sensitive design applications such as automobiles and airplanes. The design of thin shell structures has received increasing attention in both computational design and topology optimization communities over the past decades, exemplified by the differentiable simulation and inverse design of various kinds of functional shells, such as fuselage and Lotte tower\textsuperscript{[1]}, ankle-foot orthosis\textsuperscript{[2]}, blunt cone shell\textsuperscript{[3]} and etc. However, the state-of-the-art works that optimize thin-shell topology with fine features concentrate on shell topology optimization with linear elasticity. Devising methods to tackle both topological complexities and geometric nonlinearities in a unified framework remains challenging.

Researchers in mechanical engineering and scientific computing developed a host of algorithms and commercial software (e.g. Comsol\textsuperscript{[4]}) to solve thin-shell mechanics. Originated from the Mixed Interpolation of Tensorial Components (MITC)\textsuperscript{[5]} approach, one of the well-received models using triangular elements that facilitate shell analysis and design is MITC3\textsuperscript{[6]} and its nonlinear extension MITC3+\textsuperscript{[7]}. The linear\textsuperscript{[8]} and non-linear\textsuperscript{[9]} geometric effects of MITC3 have been well-studied.

On the other side, thin-shell simulation has also drawn extensive attention from computational physics and computational geometry researchers for decades, since the seminal work\textsuperscript{[10]} on discretizing and simulating elastic surfaces. A line of pioneering research has been done to devise effective variational solvers and robust time integrators to simulate shell dynamics on a triangle mesh\textsuperscript{[11-14]}. Along this line, researchers started to explore solvers based on Discrete Differential Geometry (DDG)\textsuperscript{[15]} and intrinsic shell models\textsuperscript{[16]}, where DDG developed discrete versions of fundamental concepts from differential geometry, such as curvature, tangents, and gradients, that can be applied to discrete geometric structures like meshes, graphs, and point clouds. Our shell simulator follows this line of research by discretizing the membrane and bending energy terms on a triangle mesh and solving its equilibrium by minimizing the energy.
Volumetric topology optimization has received tremendous success over the past decades \cite{17-19}. Combined with additional geometric constraints, volumetric approaches have been used to design manifold-coated structures with enclosed shells \cite{20-23}, thin sheet metal structures tailored for the deep drawing manufacturing process \cite{24}, generalized 3D non-manifold thin-walled structures \cite{25}, and sparse lattice structures \cite{26,27}. They have also been employed to produce thin features \cite{28} or cellular structures \cite{29} on a planar domain. However, none of these works leverage the shell model’s geometric feature to reduce computational cost.

Compared with the volumetric topology optimization counterpart, topology optimization on shells or other codimensional geometries has remained less explored. Early work \cite{30} started by optimizing thickness as a varying field. Ansola et al. \cite{31} introduced a parametric method to co-optimize the shell shape and topology with microstructure. A discrete material optimization framework \cite{32} later was proposed to optimize material on laminated shells, followed by extensions \cite{33,34}. There is some more recent progress made using different topology representations. Ho and Kim \cite{35} co-optimized the shape and topology of a linear thin shell using the level-set method. Other examples include NURBS \cite{36} and Moving Morphable Components (MMC) \cite{37}, series expansion \cite{38}, and multi-layer representations \cite{39} to obtain shell topology optimization results. We want also to highlight the work done by \cite{1}, which optimized shells with millions of elements on a supercomputer. Their approach produced the state-of-the-art resolution for thin-shell optimization, although with their focus on optimizing linear shells.

Despite the progress in optimizing shell structures using different topological representations, producing high-quality topology optimization designs on a geometrically nonlinear thin shell remains challenging, due to multiple interleaving difficulties in practice to simultaneously tackle the shell’s geometric nonlinearity and topological complexities to probe novel shell structural designs. In particular, due to the coupling between the shell’s bending and stretching mechanics, obtaining clear, binary structures is not a trivial task. The local minima in a nonlinear shell could exhibit features with creases, articulated joints, or a mix of surfaces and beams, which are drastically different in terms of both optimization convergence and mechanical performance from their linear and volumetric counterparts.

Several methods have been investigated to solve the convergence problem with non-linear topology optimization including using the relaxed convergence criterion \cite{39}, interpolation with linear energy \cite{40}, linear to nonlinear two-step process \cite{41}, element removal and reintroduction \cite{42,43}, and the co-rotational scheme \cite{44}. However, these methods either add on excessive computational costs or require significant implementation efforts. Similarly, our method solves the convergence issue of the thin-shell simulation within the SIMP framework by the projected Newton’s method but with minimal modification of the nonlinear structural optimization framework to keep their simulation performance.

On the other hand, a multitude of recent work in computational design and fabrication communities has been devoted to the inverse design of functional thin shells. These works can be categorized according to their physical design variables and optimization focus, including the shape-material co-optimization \cite{45}, magnetoelasticity co-optimization \cite{46}, parametric shapes \cite{47}, shell reinforcement \cite{48,49}, and synthesized microstructures \cite{50-52}, to name just a few. While they are proposed to solve different problems of inverse design, none of them has studied the topology optimization on thin shells.

We present a novel topology optimization algorithm to facilitate nonlinear structural design on thin shells. We build our approach upon state-of-the-art nonlinear DDG shell simulators stemming from previous work in computational physics and geometry \cite{15,16} and extend the framework to support differentiation calculation by adopting the projected Newton method. We further incorporate this differentiable solver into a topology optimization pipeline by equipping density representations, binary filters, and large-scale optimizers in a unified framework. Our method provides a practical tool that enables the topological design of complex and nonlinear thin-shell structures, which, to the best of our knowledge, produces state-of-the-art nonlinear shell topology optimization results in terms of their design complexity.

The rest of the paper is organized as follows. In Section 2, we introduce the thin-shell model that we adopt and the quasi-static simulation algorithm using the projected Newton method. We then formulate the topology optimization problem, derive the sensitivities with the given thin-shell model and present the optimization algorithm in Section 3. In Section 4, we validate our method by several simple cases and then demonstrate the efficacy of our method with more complicated boundary conditions, before conclusions are drawn in Section 5.

2. Thin-shell model

2.1. Continuous model

Based on the Kirchhoff–Love assumption, we model a thin shell with a mid-surface $f : \Omega \to \mathbb{R}^3$ extended by a constant thickness $h$. Here $f$ is a mapping from the two-dimensional parameter space $\Omega$ to a three-dimensional space $\mathbb{R}^3$. We represent the shell volume in terms of the shell’s mid-surface $f$ as $x(x, y, z) = f(x, y) + z\mathbf{n}(x, y)$, where $\mathbf{n}$ is the mid-surface normal, $x$ and $y$ are local coordinates in $\Omega$, $x$ is the coordinate in $\mathbb{R}^3$, and $z \in [-h/2, h/2]$ is the normal extension. The first and the second fundamental forms on $f$ are then calculated as

$$
I = \begin{bmatrix}
\frac{\partial f_x}{\partial x} & \frac{\partial f_x}{\partial y} & \frac{\partial f_x}{\partial z} \\
\frac{\partial f_y}{\partial x} & \frac{\partial f_y}{\partial y} & \frac{\partial f_y}{\partial z} \\
\frac{\partial f_z}{\partial x} & \frac{\partial f_z}{\partial y} & \frac{\partial f_z}{\partial z}
\end{bmatrix},
\quad II = -\frac{h}{12} \left( I^T - 3 \mathbf{I} \right)
$$

Following \cite{15,16}, we adopt the St. Venant–Kirchhoff model and define the elastic energy density using the first and second fundamental forms:

$$
e = \frac{h}{4} \left\| I^{-1}(1 - I) \right\|_M \sqrt{\det I} + \frac{h^3}{12} \left\| I^{-1}(1 - I) \right\|_M \sqrt{\det I}.
$$

Here, the bar notation denotes variables in the rest shape. The first term in Eq. (2) accounts for the stretching energy, and the second term represents the bending energy. We choose the material norm $\| \cdot \|_M$ by following the formula used in \cite{15} as:

$$
\| A \|_M = \frac{E}{1 - v^2} \sqrt{\text{Tr}(A)^2 + (1 - v)\text{Tr}(A^2)},
$$

where $A$ is a $2 \times 2$ matrix, $E$ is the Young’s modulus and $v$ is the Poisson’s ratio.

2.2. Differential geometry discretization

We discretize the elastic energy on a triangle mesh $(V, E, F)$, where $V$, $E$, and $F$ are the sets of vertices, edges, and faces, respectively. We assume that the physical quantities and the rest counterparts are constant over each face of the triangle mesh. Following \cite{16} adopting the use of DDG, for a triangle with vertices $i, j, k$, we discretize $x(x, y)$ and $\mathbf{n}(x, y)$ into

$$
I_{ijk} = \left\| (v_j - v_i)^2 \left( v_j - v_i \right) \cdot (v_k - v_i) \right\|_2,
$$

and

$$
I_{ijk} = \frac{1}{6} \left( (n_j - n_i) \cdot (v_j - v_i) \left( n_j - n_i \right) \cdot (v_k - v_i) - (n_k - n_i) \cdot (v_j - v_i) \left( n_k - n_i \right) \cdot (v_k - v_i) \right),
$$

where $(n_i, n_j, n_k)$ are the mid-edge normal. We can also compute the rest first and second fundamental forms analogously for a given rest configuration $(\mathbf{\theta}_i, \mathbf{\theta}_j, \mathbf{\theta}_k)$ and $(\mathbf{\theta}_i, \mathbf{\theta}_j, \mathbf{\theta}_k)$. Then it is straightforward to write down a discrete elastic energy density for each triangle by substituting (4) and (5) into (2).
2.3. Quasi-static simulation

We devise a quasi-static solver to minimize the elastic energy defined in Eq. (2) with given boundary conditions and external loads. Solving the quasi-static system using the implicit Euler scheme amounts minimizing the total potential energy \( \varepsilon' = e - f_{\text{ext}} \cdot x \) on a discrete shell, which is nonlinear w.r.t. the vertex positions. We devised an iterative solver based on the Newton–Raphson method with a backtracking line search to find the solution with more numerical stability. As shown in Algorithm 1, in each iteration we first compute the total potential energy and the corresponding gradients and Hessian. Since the energy, derivatives, and Hessian are calculated on each triangle separately, we can easily parallelize the computation using multi-threads on the CPU to reach high computational efficiency, using OpenMP [53]. The system’s Hessian matrix needs to be positive semi-definite (PSD) to ensure the algorithm searches in an energy-descending direction. We devise a mesh-independent density filter and a density filters. The first pass we employed is to smooth the density field. The optimization problem. Given a domain \( \Omega \), we formulate the topology optimization problem as minimizing the structural compliance \( e(p, u) \) by optimizing \( p \), when the force equilibrium of internal force \(-\partial e/\partial u\) and external force \( f_{\text{ext}} \) is reached:

\[
\min_p e(p, u), \quad \text{subject to} \quad \begin{cases}
\frac{V(p)}{V(\Omega)} \leq f_v, \\
Du = 0, \\
\frac{\partial u}{\partial n} = f_{\text{ext}},
\end{cases}
\]

where \( u \) is the displacement, \( V(p) \) is the material volume, \( V(\Omega) \) is the volume of the design domain, \( f_v \) is the input volume fraction constraint, \( D \) is a selection matrix assigning Dirichlet boundary conditions to mesh nodes.

3. Topology optimization

3.1. Problem formulation

**Design variables.** We define a density value \( \rho \in [0, 1] \) on each triangle. Following the modified Solid Isotropic Material with Penalization (SIMP) method [17], Young’s modulus of each triangle is calculated as a function of input density with a constant penalizing power \( p \) as:

\[
E(\rho) = E_{\text{min}} + \rho^p (E_0 - E_{\text{min}}),
\]

where \( E_{\text{min}} \) and \( E_0 \) are constants specifying the minimum and maximum Young’s modulus, and \( p \) is a scalar field discretizing the density distribution over triangles. If filters are further applied on \( \rho \), Eq. (6) will take the projected density as input. We choose \( E_{\text{min}} = 1e^{-4}E_0 \), \( E_0 \) specified in the Table 1 and \( p \) varies according to description in Section 3.3.

Optimization problem. Given a domain \( \Omega \), we formulate the topology optimization problem as minimizing the structural compliance \( e(p, u) \) by optimizing \( p \), when the force equilibrium of internal force \(-\partial e/\partial u\) and external force \( f_{\text{ext}} \) is reached:

\[
\min_p e(p, u), \quad \text{subject to} \quad \begin{cases}
\frac{V(p)}{V(\Omega)} \leq f_v, \\
Du = 0, \\
\frac{\partial u}{\partial n} = f_{\text{ext}},
\end{cases}
\]

where \( u \) is the displacement, \( V(p) \) is the material volume, \( V(\Omega) \) is the volume of the design domain, \( f_v \) is the input volume fraction constraint, \( D \) is a selection matrix assigning Dirichlet boundary conditions to mesh nodes.

**Density filters.** We devised a mesh-independent density filter and a projection filter to coerce the density field towards forming a clear structure. The combination of these two steps also avoids checkerboard artifacts. The first pass we employed is to smooth the density field. Motivated by [56], we calculate a weighted average density based on triangles within a certain range. For a given triangle, our filter is calculated as:

\[
\hat{\rho}_k = \frac{\sum_{i \in N_k} w_i \rho_i v_i}{\sum_{i \in N_k} w_i v_i},
\]

which blends the densities within a spherical neighborhood specified by the radius \( r \). Here \( N_k \) is the 4th element of the neighbor list within \( r, v_i \) is the triangle area, and \( \phi_i \) is the triangle density. For the second pass, we apply a projection filter to obtain a binary result of the final density field on the triangle mesh. Our scheme was motivated by the projection approach used in volumetric topology optimizations (e.g. [57]) to obtain a clear structure. The projection filter takes \( \hat{\rho} \) as the input from the previous filter and calculates the projected density \( \bar{\rho} \) as:

\[
\bar{\rho}_k = \frac{\tanh(\gamma \rho) + \tanh(\gamma(\hat{\rho}_k - \eta))}{\tanh(\gamma(1 - \eta)) + \tanh(\gamma(1 - \eta))},
\]

where \( \eta = 0.5 \) is the density threshold and \( \gamma \) controls how strong the projection is. When \( \gamma = 1 \), there is no projection. In our implementation, we use \( \gamma \in [1, 16] \). Last, we set the projected density value \( \bar{\rho} \) as the input of Eq. (6) to update Young’s modulus of each triangle.

Algorithm 2 Thin Shell Topology Optimization

1. \( p \leftarrow 1, \gamma \leftarrow 1, \rho_{\text{ext}} \leftarrow f_{\text{ext}} \forall e \in \Omega \\
2. for \ i \leftarrow 1 \ to \ max_{\text{iterations}} \ do \\
3. \quad \text{Increment } p \ and \ \gamma \ with \ the \ continuation \ scheme \\
4. \quad \text{Update } x \ according \ to \ Algorithm \ 1 \\
5. \quad \text{Calculate } e \ using \ Equation \ (2) \\
6. \quad \text{Calculate } V(p) \\
7. \quad \text{Update } \frac{\partial e}{\partial \rho} \ and \ \frac{\partial^2 e}{\partial \rho^2} \ using \ Equation \ (18) \ and \ (19) \\
8. \quad \rho_{\text{u1}} \leftarrow \text{mma_update}(\rho, \Delta \rho_{\text{u}}, V(p), \frac{\partial^2 e}{\partial \rho^2}, \text{move_limit}) \\
9. \quad \Delta \rho \leftarrow \rho_{\text{u1}} - \rho_1 \\
10. \quad \text{if } \|\Delta \rho\|_{\infty} < tol \ then \\
11. \quad \quad \text{break} \quad \triangleright \ tol = 1e^{-4} \\
12. \quad \text{end if} \\
13. \quad \text{Update } \rho \ using \ Equation \ (8) \ and \ (10) \\
14. \quad \text{end for} \\
15. \end for
By taking the partial derivative of $\rho$ and right multiplying $[\partial^2 e(u, \rho) / \partial u^2]^{-1}$ for the Eq. (11), we derive the partial derivative of $u$ with respect to $\rho$ as follows

$$\frac{\partial u}{\partial \rho} = \frac{\partial^2 e(u, \rho)}{\partial \rho \partial u} \left[ \frac{\partial^2 e(u, \rho)}{\partial u^2} \right]^{-1}. \tag{12}$$

Substituting (12) into the total derivative of objective $e$ w.r.t. $\rho$

$$\frac{\partial e(u, \rho)}{\partial \rho} = \frac{\partial e(u, \rho)}{\partial \rho} + \frac{\partial u}{\partial \rho} \frac{\partial e(u, \rho)}{\partial u} \tag{13}$$

yields

$$\frac{\partial e(u, \rho)}{\partial \rho} = \frac{\partial e(u, \rho)}{\partial \rho} + \frac{\partial^2 e(u, \rho)}{\partial \rho \partial u} \left[ \frac{\partial^2 e(u, \rho)}{\partial u^2} \right]^{-1} \frac{\partial e(u, \rho)}{\partial u}. \tag{14}$$

Notice that we do not calculate the inverse of the matrix directly. Instead, we convert $[\partial^2 e(u, \rho) / \partial u^2]^{-1}$ into solving the linear system and solve it with the CHOLMOD solver as what we did in the forward simulation. Using (6), (14) can be simplified as

$$\frac{\partial e}{\partial \rho_k} = p_k \delta_k^p \cdot \epsilon_k. \tag{15}$$

From (10), we have

$$\frac{\partial \tilde{\rho}_k}{\partial \phi_j} = \frac{1}{\tan(\rho(\tilde{\rho}_k - \eta)^2)} \left( \frac{1}{\tan(\eta) + \tan(\rho(1 - \eta))} \right)$$

Here, $\frac{\partial \tilde{\rho}_k}{\partial \phi_j}$ is calculated using (8) as

$$\frac{\partial \tilde{\rho}_k}{\partial \phi_j} = \sum_{j \in N_e} w_k \epsilon_j \tag{17}$$

Following the chain rule, the derivative of objective $e$ w.r.t design variables $\phi$ is

$$\frac{\partial e}{\partial \phi_j} = \frac{\partial e}{\partial \tilde{\rho}_k} \frac{\partial \tilde{\rho}_k}{\partial \phi_j}. \tag{18}$$

The derivative of volume $V(\rho_e)$ w.r.t. $\phi_j$ is simply the volume of each element times $\frac{\partial \rho_e}{\partial \phi_j}$ and $\frac{\partial \rho_e}{\partial \phi_j}$, following the chain rule as

$$\frac{\partial V(\rho_e)}{\partial \phi_j} = V(\tilde{\rho}_e) \frac{\partial \tilde{\rho}_e}{\partial \phi_j}. \tag{19}$$

3.3. Optimization

Given the sensitivities for the objective and constraints, we use the method of moving asymptotes (MMA) [58,59] to optimize the densities on triangles to minimize the shell’s elastic compliance. Following Algorithm 2, we first initialize the penalization power $p$ and the density projection parameter $\gamma$ to 1. In each iteration, we then run the quasi-static thin-shell simulation according to Algorithm 1 to reach a balance between internal and external forces under the current density distribution. On Line 5, to achieve better density convergence we use the continuation strategies as [60] by increasing $p$ by 0.05 every other iteration when $p$ is smaller than 2 and once every five iterations when $p$ is smaller than 3. Similarly, we double $\gamma$ once every 10 iterations after 200 iterations until it reaches 16. Then we calculate the sensitivities for the objective and constraint functions according to Eqs. (18) and (19) to update the optimization variables. Also, we do not perform a direct inversion on the global Hessian matrix but solve for $\frac{\partial^2 e}{\partial \rho^2}$ with the corresponding linear system by Eq. (12). The Hessian is calculated the same as what we do in the quasi-static simulation except that we do not project the Hessian to PSD here and switch to a direct sparse LU solver when the CHOLMOD solver fails to solve the system, in order to achieve more accurate gradients while keeping the solving efficiency at the same time. We update $\rho$ with the MMA optimizer and check for convergence. The move-limit on Line 8 indicates how much the variable can change, which we use 0.1 in all experiments.

4. Numerical results

All examples were run on a single desktop with an AMD Ryzen 7 3800X 8-Core 3.90 GHz processor and 64 GB installed RAM. The experiment parameters and statistics are summarized in Table 1. Use the compliance convergence criteria $\sum_{i \in \{x, y, z\}} e_i^2 + e_{\text{xx}} + e_{\text{yy}} + e_{\text{zz}} < 1\%$ (script

To summarize, we used a hybrid approach incorporating linear and nonlinear elements to accurately model the thin-walled structures. Our simulation framework, named Thin-Walled Structures (TWS), achieved competitive runtimes while maintaining high accuracy through the integration of advanced optimization techniques and efficient solvers.
Fig. 2. The convergence plots for the long beam examples.

Fig. 3. Top: the long beam structure produced by using linear MITC elements in COMSOL with $\|f_{\text{ext}}\| = 100$ N. Bottom: the deformed structure simulated using our geometrically nonlinear simulator with an objective equal to 3.59.

denotes iteration), all our examples converge within 125 iterations. The convergence plots for all examples also demonstrate good convergence. We show the results at iteration 250 after the designs become the most binary.

4.1. Validation

First, we validate the correctness of our method under different loading conditions with three examples and compared the results with other standard methods.

Long beam: validation for in-plane force. As shown in Fig. 1, we demonstrate that our method can produce optimization results under in-plane point force loads with different magnitudes to explore the material’s geometric non-linearity. In a $4 \times 0.5 \text{ m}$ domain with $0.001 \text{ m}$ thickness, we set up a 160k triangle mesh based on an $800 \times 100$ grid with left and right nodes fixed. A point force pointing downward is added on the bottom middle node of the plane. The convergence plot of this example is shown accordingly in Fig. 2, from which we can tell that all optimizations converge within 100 iterations. The initial rise in objective was due to the use of the continuation of the parameter scheme for $\rho$. As the force becomes larger, there are fewer detailed structures formed and buckling happens in the middle of the beam when $\|f_{\text{ext}}\| = 100$ N. As the force becomes larger, the strain enters the geometrically non-linear region and the structure becomes more degenerated and only supports well for the specific load case. The transition of structures from thin patterns to thick beams under different in-plane loads is consistent with the beam structures obtained by other standard nonlinear topology optimization algorithms using volumetric elements (e.g. [61]).

To further validate the correctness of our in-plane model, we further compared the results with the linear MITC3 elements in COMSOL. As shown in Fig. 3, the long rectangular domain is similarly fixed on both sides and a 100 N external force load is applied on the bottom middle node. The optimized structure is similar to the structure that we optimized using a small force load equal to 0.01 N. This structure produces a much larger objective (3.59) than that of our structure (0.560) when both are simulated with geometrically nonlinear elements (see Fig. 5).
Fig. 8. Paraboloid shell. Optimization iteration from left to right, top to bottom: 0, 20, 100, 250.

Fig. 9. The convergence plot of the paraboloid shell example.

Fig. 10. Left is the concave hyperboloid cylinder and right is the convex hyperboloid cylinder. The inset picture indicates the boundary condition.

**Bending plane: validation for out-of-plane force.** In this example, we demonstrate that our method can optimize structures with purely out-of-plane forces, see Fig. 4. We set a triangulated $128 \times 64$ plane fixing the left ten percent of the plane nodes and add 100 N on the rightmost nodes with the density $\rho$ of the rightmost faces fixed at 1. Since the displacement is very large for this example, we decrease the tolerance for simulation tolerance to 0.1 of the typical edge length for faster convergence. Before the structural optimization, the plane with evenly distributed density is bent downwards. As optimization proceeds, densities are mostly gathered towards the left side of the structures and only minimum densities are allocated to form a connection with the force loads. Therefore, as shown in the convergence plot Fig. 5, the bending energy is largely reduced and a crease traverses through the middle of the optimization domain.

Fig. 11. Left: the convergence plot of the concave hyperboloid cylinder. Right: the convergence plot of the convex hyperboloid cylinder.

Fig. 12. Optimization intermediate states of the Stanford bunny at iteration 1, 20, 100 and 250. The boundary condition is indicated in the first picture, where the bottom nodes of the bunny are fixed and loads are applied on the head and the back.

Fig. 13. The convergence plot of the bunny example.

**Cylinder pulled from two sides: validation for large deformation.** With the top and bottom nodes fixed, we add two loads of vertically distributed forces on the sides concentrating on the middle 0.5 of the cylinder height. The cylinder is 3 m tall with a radius equal to 1 m. As demonstrated in Fig. 6, there is subtle deformation can be observed initially,
where the two sides are pulled by forces. At the end of the optimization, we can see two clear “X” shapes forming around the applied force while connecting the top and bottom fixed nodes. Notice that there is a vertical gap formed in each of the x shapes, which acts as a hinge so that the overall bending energy can be minimized, see plot in Fig. 7.

4.2. Examples

Next, we demonstrate that our method can generate intricate structures on complex geometries under various loading conditions.

Paraboloid shell. We set up a 215k triangle mesh with a paraboloid shape with $y = -0.5((x - 0.5)^2 + (z - 0.5)^2)$, where $x, z \in [0, 1]$. The four corners of the mesh are fixed and a downward point load of 0.0001 N is added in the center of the mesh. As shown in Fig. 8, our method first distributes the density mostly in the middle and around the four edges and then generates thin beams connecting the middle part with the four corners. The convergence plot is shown as Fig. 9, from which we can observe the increase of objective before iteration 50 due to the effect of the continuation of the parameter scheme.

Hyperboloid cylinder. By fixing the bottom of the hyperboloid cylinder nodes and adding a distributed load of 0.0001 N on the top, we optimize the density distribution on concave and convex hyperboloid cylinders which are both 3 m tall, see Fig. 10. The concave cylinder produces a network consisting of connecting rhombi while the convex cylinder produces a network consisting of rectangles. The optimizer automatically generates the solid ring on the top of the cylinders to maximize the stiffness around the force load. These two patterns match the design of durable stools in the real world. The convergence plots are given in 11.

Stanford bunny. Our method also works on more complex geometries like the Stanford bunny, shown in Fig. 12 with the convergence plot in Fig. 13. We fixed the bottom nodes of the bunny and applied distributed loads of 0.1 N on the head and the back of the bunny. Concentrated density formed around the head and the back area where the force loads are applied, while grid-like structures span around the chest and buttock area.

Fig. 14. Odonata wing optimization results with two different loading cases.

Fig. 15. Left: the convergence plot of the Odonata wing example with pulling force on the bottom right boundary. Right: the convergence plot of the Odonata wing example with downward pushing forces on the entire domain.

Odonata wing. In this example, we show that our method can produce detailed vein-like structures on an Odonata wing with out-of-plane forces. In Fig. 14 with convergence plots in Fig. 15, the design domain is a shell shaped like the Odonata wing with the middle nodes lifted a small amount (as illustrated by the inset of the bottom figure). The leftmost nodes on the boundary are fixed in both cases which is similar to how wings are attached on odonata. In the top figure, the distributed loads are applied on the right bottom boundary nodes along the normal direction with 5 degrees of out-of-plane component into the image plane. Long beams with high densities are formed in the middle and bottom of the plane, traversing horizontally and tapering towards the right end. In the bottom figure, distributed forces pointing into the image plane with a linear increment from left to right are applied to every node. We observe that a main beam travels horizontally in the middle and it branches out like fractals over the entire domain. Although in real life, the force load applied to the Odonata wing is constantly changing, here we provide the optimized structure under two arbitrary loads with out-of-plane force components to obtain some insights.

5. Conclusion

This paper presents a nonlinear topology optimization algorithm on thin shells to obtain complex structures. The algorithm embodied a differentiable, nonlinear thin shell solver to carry out sensitivity
analysis and density evolution on a shell mesh. A density filter was designed to coerce binary structures. We validated our approach on different test scenarios of optimizing nonlinear structures, exploring the bending-stretching tradeoff, and large nonlinear deformation, as well as generating high-resolution shell structures.

Currently, our approach has several aspects of limitations. First, our thin-shell solver cannot handle element inversion, hindering it from solving shells with a large in-plane compression. Strain-limiting methods or inelastiv elastic solvers (e.g., [54]) will be considered to enhance the robustness of the current method. Second, our method does not optimize shape. Due to the algorithmic complexities of updating mesh elements, it is currently challenging to co-optimize mesh geometry and topology in a unified framework. It will be interesting to further explore thin-shell solvers that can work on other shell representations such as particles and implicit surfaces to explore the possibilities of shape-density co-optimization. Third, devising high-performance multigrid shell solvers is also an immediate next step to facilitate super-resolution shell optimization. Last, our current method does not support nonmanifold geometries, which prevents the tackling of many interesting shell structures such as foams and bubble clusters. One of our future directions is to explore the nonmanifold shell solver and its topology optimization.

CRediT authorship contribution statement

Fan Feng: Writing – review & editing, Writing – original draft, Visualization, Software, Methodology, Investigation, Conceptualization. Shiying Xiong: Writing – original draft, Conceptualization.
